Continued disappearance of the benthic amphipod Diporeia spp. in Lake Michigan: is there evidence for food limitation?

Thomas F. Nalepa, David L. Fanslow, Andrew J. Foley, III, Gregory A. Lang, Brian J. Eadie, and Michael A. Quigley

Abstract: Benthic surveys were conducted in the southern basin of Lake Michigan and throughout the lake to assess trends in benthic populations, emphasizing recent changes in densities of the benthic amphipod Diporeia spp. and dreissenid mussels. In the southern basin, Diporeia populations declined 89%, 91%, and 45% between 1993 and 2002 at sites <30, 31–50, and 51–90 m, respectively. Lakewide, the population declined 65% between 1994–1995 and 2000. Over the same time period, dreissenid densities, particularly Dreissena bugensis, increased. Intensive studies at 45 m sites in the southeastern region examined changes in lipid content, age structure, and benthic food inputs relative to the hypothesis that food limitation was a factor in Diporeia’s disappearance. As Diporeia densities declined to zero, length–weight remained unchanged, and lipid content generally increased. Recruitment still occurred, but the young did not survive to become adults. Based on organic carbon, biogenic silica, and chlorophyll collected in sediment traps and found in the upper sediments, pelagic inputs to the benthic region still occurred. Our field observations and laboratory experiments did not disprove the hypothesis that food limitation from dreissenid filtering activities was the cause of the decline, but direct relationships between the loss of Diporeia and indicators of food availability were difficult to establish.

Résumé : Nous avons inventorié le benthos dans le bassin sud du lac Michigan ainsi que dans le lac dans son ensemble afin de déterminer les tendances dans les populations benthiques, en particulier les changements récents de densité de l’amphipode benthique Diporeia spp. et des bivalves dreissénidés. Dans le bassin sud de 1993 à 2002, les populations de Diporeia ont diminué respectivement de 89 %, 91 % et 45 % dans les sites situés à <30, 31–50 et 51–90 m, respectivement. À l’échelle du lac, les populations ont diminué de 65 % entre 1994–1995 et 2000. Durant la même période, les densités des dreissénidés, particulièrement de Dreissena bugensis, ont augmenté. Des études poussées aux sites de 45 m ont évalué les changements du contenu lipidique, de la structure d’âge et des apports de nourriture benthique en relation avec l’hypothèse voulant que la carence de nourriture soit un facteur dans la disparition de Diporeia. Au moment où les densités de Diporeia déclinaient vers zéro, la relation longueur–masse est restée inchangée et le contenu lipidique a en général augmenté. Il y avait encore du recrutement, mais les jeunes ne survivaient pas jusqu’à l’âge adulte. D’après les mesures de carbone organique, de silice biogénique et de chlorophylle effectuées dans les pièges à sédiments et dans les sédiments superficiels, il y avait encore des apports pélagiques vers la région benthique. Nos observations de terrain et nos expériences de laboratoire ne permettent pas de rejeter l’hypothèse d’une limitation alimentaire causée par les activités de filtration des dreissénidés comme cause du déclin, mais il est difficile d’établir des liens directs entre la perte des Diporeia et les indicateurs de disponibilité de nourriture.

Introduction

The increased spread of aquatic invasive species has led to the growing realization that these invaders, either individually or in concert, can change ecosystems at many levels of organization (Simon and Townsend 2003). A striking example is the Great Lakes ecosystem, where over the past 10–15 years, species invasions have led to the loss of native species, altered pathways of energy and nutrient flux through food webs, and redefined fundamental understanding of ecosystem function (Nalepa et al. 1996; Vanderploeg et al. 2002; Hecky et al. 2004). When considering imposed changes within the Great Lakes, perhaps the most large-scale, and certainly the most equivocal, has been the disap-
pearance of the deepwater amphipod *Diporeia* spp. Declines in *Diporeia* populations have recently been documented in all the lakes except Lake Superior, and large areas in southeastern Lake Michigan (Nalepa et al. 1998), outer Saginaw Bay, Lake Huron (Nalepa et al. 2003), eastern Lake Erie (Dermott and Kerc 1997), and Lake Ontario (Dermott 2001; Lozano et al. 2001) are now mostly devoid of this organism.

*Diporeia* are part of a deepwater fauna that inhabit cold, proglaciated lakes, brackish estuaries, and coastal margins in the holarctic region (Bousfield 1989). Prior to its decline, *Diporeia* were the most abundant benthic macroinvertebrate in the deeper regions of all the Great Lakes, comprising >70% of all benthic biomass at depths greater than 30 m (Cook and Johnson 1974; Nalepa 1989). *Diporeia* were also present but less dominant in nearshore regions (<30 m) of the open main basins and naturally absent from the shallow, warm bays and basins (i.e., inner Green Bay, inner Saginaw Bay, western and central Lake Erie). As an infaunal detritivore, *Diporeia* burrow in the upper 2 cm of sediment and feed mainly on organic material freshly settled from the water column (i.e., mostly diatoms). Feeding rates reach a seasonal maximum during and just after the spring diatom bloom, and populations can consume a large portion of energy inputs to the benthic region during this period (Dermott and Corning 1988; FitzGerald and Gardner 1993).

*Diporeia*, in turn, are fed upon by most fish species found in the offshore waters of the Great Lakes, including slimy and deepwater sculpin (*Cottus cognatus* and *Myoxocephalus thompsonii*, respectively), alewife (*Alosa pseudoharengus*), bloater (*Coregonus hoyi*), lake whitefish (*Coregonus clupeaformis*), yellow perch (*Perca flavescens*), and rainbow smelt (*Osmerus mordax*) (Anderson and Smith 1971; Scott and Crossman 1973; Wells 1980). As such, it serves as an important pathway by which energy fixed as primary production is cycled to upper trophic levels.

Declines of *Diporeia* populations in the Great Lakes were first noted in the early 1990s, and in all lake areas, these declines were coincident with the introduction and spread of the invading species *Dreissena polymorpha* (zebra mussel) and *Dreissena bugensis* (quagga mussel). A common hypothesis for the decline is that dreissenids are outcompeting *Diporeia* for available food (Nalepa et al. 1998; Dermott 2001). Dreissenids filter-feed near the sediment surface, and this hypothesis assumes that settling organic material is intercepted by dreissenids before it reaches the upper sediments and becomes available to *Diporeia*. Deepwater amphipods such as *Diporeia* (neararctic) and the closely related *Monoporeia affinis* (palearctic) are generally food-limited, and both short- and long-term population trends have been attributed to changes in pelagic food inputs to the benthic region (Sarvala 1986; Johnson and Wiederholm 1992; Goedkoop and Johnson 2001). Yet despite the broad negative response of *Diporeia* to *Dreissena*, there are inconsistencies when examining decline patterns relative to the food-limitation hypothesis. For one, *Diporeia* populations have disappeared from several areas in the Great Lakes that were far-removed from dreissenid colonies and where potential food was still present in overlying waters and presumed to be settling to the bottom (Dermott 2001; Nalepa et al. 2003). Also, *Diporeia* are still abundant in some areas despite the presence of dreissenids (Dermott et al. 2005).

In this paper, we document recent spatial and temporal trends of *Diporeia* populations in Lake Michigan relative to expanding numbers of dreissenids. We also examine changes in age structure, physiological well-being, and pelagic food inputs during periods of population loss. These changes were compared with similar observations made prior to the introduction of dreissenids and *Diporeia* declines. Moreover, we conducted laboratory experiments to provide insights into our field observations and to further explore the food-limitation hypothesis.

**Materials and methods**

**Spatial and temporal trends in densities**

To document long-term spatial and temporal trends in densities of *Diporeia* and *Dreissena* in Lake Michigan, benthic samples were collected over several time periods at sites located in the southern basin and also at sites located throughout the entire lake. In the southern basin, samples were collected at 40 sites in 1998–2002 (Fig. 1). Bottom substrates at the sites ranged from coarse sand and gravel to fine silt, and depths ranged from 16 to 157 m. These 40 sites are part of a long-term monitoring program of the total macroinvertebrate community and have been sampled for 2 consecutive years every 5 years between 1980 and 1993 (Nalepa 1987; Nalepa et al. 1998). Consistent with this program, samples were again collected at these sites in 1998–1999. In 2000–2002, samples were collected at the same 40 sites and at 13 additional sites (A-4, C-2, C-45, F-2, F-3, G-45, K-2, N-2, N-3, T-3, M-45, R-45, SAU-45; Fig. 1). Whereas data from all 53 sites were used to better define spatial distributions of *Diporeia* and *Dreissena* in each of the 3 years, only data from the original 40 sites were used when examining temporal trends. Samples in 1998–1999 were collected in spring (mid-May to early June), summer (late July to early August), and fall (September to October), but in 2000–2002, samples were collected only in fall. For analysis purposes, sites were divided into four depth intervals: 16–30, 31–50, 51–90, and >90 m. These depth intervals are consistent with prior characterization of depth–macroinvertebrate associations in Lake Michigan (Nalepa 1987).

Densities of *Diporeia* and *Dreissena* were determined throughout Lake Michigan by sampling at 158 sites in late summer–fall 2000. Besides the 53 sites sampled in the southern basin, an additional 105 sites were sampled in the central and northern basins, Green Bay, and Grand Traverse Bay. Many of these sites (42 of 105) were sampled previously in 1994–1995 (Nalepa et al. 2000).

Methods of collection and analysis were the same for all sampling periods. Sediment samples were taken in triplicate with a Ponar grab (area = 0.046 m²) at each site and washed into an elutriation device fitted with a nitex sleeve with 0.5 mm openings. Retained material was immediately preserved in 5% buffered formalin containing Rose Bengal stain. In the laboratory, all macrobenthic organisms in the 1998–1999 samples were picked, counted, and sorted into major taxonomic groups (Amphipoda, Oligochaeta, Chironomidae, *Dreissena*, Sphaeriidae) under a low-power magnifier lamp.
Chironomidae densities were low as in previous years and therefore not reported here. Only *Diporeia* and *Dreissena* were enumerated in samples collected in 2000–2002.

For the southern basin, differences in densities of *Diporeia* and *Dreissena* over the 1992–2002 period, as well as differences in densities of Oligochaeta and Sphaeriidae over the 1992–1999 period, were tested using a two-way analysis of variance (ANOVA; year × depth interval) on individual replicates. For the lakewide surveys in 1994–1995 and 2000, density differences of *Diporeia* and *Dreissena* were tested using a two-way ANOVA as above (period × depth interval). Additionally, the lake was divided into south, central, and north regions (Nalepa et al. 2000), and a two-way ANOVA (year × region) was used to test differences separately within each depth interval. For all ANOVAs in the southern basin and lakewide surveys, the data were log-transformed (ln + 1) to homogenize variances and post hoc multiple-range tests (Tukey’s honestly significant difference (HSD)) were performed using Bonferroni-adjusted $p$ values.

Population age structure, physiological condition, and physical variables

Soon after it became apparent that the *Diporeia* population in the southern basin was declining (Nalepa et al. 1998), we initiated a monthly sampling program in 1997 at four sites in the southeastern portion of the lake to document trends in age structure, lipid content, and length–weight and also to document relative amounts of potential food settling to the benthic region. The sites were located at 45 m water depth off St. Joseph (H-22; 42°08.35N, 86°39.83W), Saugatuck (SAU-45; 42°41.14N, 86°18.90W), Grand Haven (H-31; 43°02.47N, 86°19.99W), and Muskegon (M-45; 43°11.27N, 86°25.78W) (Fig. 1). Based on sampling prior to 1997, we knew that the state of populations at these four sites varied widely. The population had already disappeared at H-22, was present but declining at SAU-45 and H-31, and was still abundant at M-45. Both H-22 and H-31 were part of our long-term monitoring program, and SAU-45 was located near a long-term monitoring site of similar depth (B-2).
Samples for density estimates of *Diporeia* and *Dreissena* at H-31 had also been collected one to four times per year in 1994, 1995, and 1996. In 1997 and 1998, Ponar samples at all four sites were collected monthly from late March–April to late October–November. After 1998, monthly sampling continued at sites where *Diporeia* were still present and lasted until it was no longer found.

Beginning in 1994 at H-31 and in 1997 at the other 45 m sites, body lengths of *Diporeia* in each of the replicate samples were determined by first tracing individuals (body midline) under 12× magnification using a camera lucida and then measuring tracings with a digitizer (Quigley and Lang 1989). Measurements were made from the base of the rostrum to the tip of the telson. In replicates with high numbers of individuals, animals were subsampled using a Folsom plankton splitter, and lengths were determined on at least 75–100 animals. In addition, body lengths were determined on animals in Ponar grabs collected monthly (April to November) at H-31 in 1986–1988. For these samples, all individuals in one replicate grab were measured. After lengths were determined, animals were placed into three size categories: 0–3, 3–5, and >5 mm. At depths of about 45 m in the Great Lakes, these sizes represent newly recruited young (YOY), juveniles, and adults, respectively (Winnell and White 1984; Johnson 1988).

On each sampling date beginning in 1994, extra Ponar grabs were taken at each site for the determination of *Diporeia* lipid content and length–weight. Upon collection, entire grab samples (animals, sediments, and overlying waters) were placed into plastic bags and kept cool during transport back to the laboratory. Within 24 h of collection, 20–25 juveniles and adults were placed individually into preweighed minitest tubes (6 mm × 50 mm). For YOY, 5–10 individuals were placed into each tube (3–5 replicates). Before animals were placed into the tubes, individual body lengths were traced and later measured. The animals were dried for 48 h (under N\(_2\) at 50–60 °C) and then stored frozen under vacuum until lipid extraction. Animals were reweighed just prior to lipid extraction, and individual animal weights were used to derive length–dry weight relationships. For YOY, mean length and weight were used in derived relationships. Total lipids were extracted using chloroform–methanol (2:1), quantified and weight were used in derived relationships. Total lipids and 75–100 animals. In addition, body lengths were determined on animals in Ponar grabs collected monthly (April to November) at H-31 in 1986–1988. For these samples, all individuals in one replicate grab were measured. After lengths were determined, animals were placed into three size categories: 0–3, 3–5, and >5 mm. At depths of about 45 m in the Great Lakes, these sizes represent newly recruited young (YOY), juveniles, and adults, respectively (Winnell and White 1984; Johnson 1988).

On each sampling date beginning in 1994, extra Ponar grabs were taken at each site for the determination of *Diporeia* lipid content and length–weight. Upon collection, entire grab samples (animals, sediments, and overlying waters) were placed into plastic bags and kept cool during transport back to the laboratory. Within 24 h of collection, 20–25 juveniles and adults were placed individually into preweighed minitest tubes (6 mm × 50 mm). For YOY, 5–10 individuals were placed into each tube (3–5 replicates). Animals were reweighed just prior to lipid extraction, and individual animal weights were used to derive length–dry weight relationships. For YOY, mean length and weight were used in derived relationships. Total lipids were extracted using chloroform–methanol (2:1), quantified and weight were used in derived relationships. Total lipids and 75–100 animals. In addition, body lengths were determined on animals in Ponar grabs collected monthly (April to November) at H-31 in 1986–1988. For these samples, all individuals in one replicate grab were measured. After lengths were determined, animals were placed into three size categories: 0–3, 3–5, and >5 mm. At depths of about 45 m in the Great Lakes, these sizes represent newly recruited young (YOY), juveniles, and adults, respectively (Winnell and White 1984; Johnson 1988).

On each sampling date beginning in 1994, extra Ponar grabs were taken at each site for the determination of *Diporeia* lipid content and length–weight. Upon collection, entire grab samples (animals, sediments, and overlying waters) were placed into plastic bags and kept cool during transport back to the laboratory. Within 24 h of collection, 20–25 juveniles and adults were placed individually into preweighed minitest tubes (6 mm × 50 mm). For YOY, 5–10 individuals were placed into each tube (3–5 replicates). Before animals were placed into the tubes, individual body lengths were traced and later measured. The animals were dried for 48 h (under N\(_2\) at 50–60 °C) and then stored frozen under vacuum until lipid extraction. Animals were reweighed just prior to lipid extraction, and individual animal weights were used to derive length–dry weight relationships. For YOY, mean length and weight were used in derived relationships. Total lipids were extracted using chloroform–methanol (2:1), quantified gravimetrically, and reported as percent dry weight (Gardner et al. 1985a). Differences in lipid content between years and age classes were examined with a two-way ANOVA after arcsine transformation.

Sediment traps were deployed at the 45 m sites to measure potential pelagic inputs to the benthic region. In 1997, settling material was collected with a sequencing sediment trap that consisted of a cylinder with a 20 cm opening and 8:1 aspect ratio (Muzzi and Eadie 2002). A bottom funnel led to an attached array of twenty-three 60 mL bottles within a rotating carousel. The carousel was programmed to rotate so a new bottle collected every 9 days. Before deployment, each bottle was filled with 30 mg mercuric chloride to prevent microbial activity. The traps were deployed just below the thermocline (30 m water depth) from March – early April to October 1997 at SAU-45, H-31, and M-45. In 1998 and 1999, sediment traps consisted of a cylinder with an opening of 10 cm and an aspect ratio of 5:1. The cylinder had a funnel at the bottom connected to a 500 mL bottle that had 20 mL chloroform as a preservative. Intercalibrations showed these traps collected at the same rate as the sequencing traps deployed in 1997 (Muzzi and Eadie 2002). Traps were deployed at all four 45 m sites in 1998 and at H-31 and M-45 in 1999. Traps were retrieved and bottles replaced on a monthly basis between March – early April and October.

After retrieval, collected material was poured through a 500μm screen to remove benthos and large zooplankton and then allowed to settle for at least 24 h before the supernatant was decanted. The samples were then freeze-dried and kept frozen until analysis. Total organic carbon (TOC) was analyzed with a Carlo Erba CHN elemental analyzer. Prior to analysis, subsamples for TOC were treated with 2 mol·L\(^{-1}\) HCl, shaken for 24 h, and then dried at 60 °C to remove mineral carbonates. Chlorophyll *a* (Chl) was determined according to the method of Hansson (1988). Biogenic silica (BiS) was determined by first using a wet alkaline method for digestion and then measuring concentrations of SiO\(_2\) with an Alpkem FS3000 analyzer (Krausse et al. 1983).

During each monthly sampling in 1998, an extra Ponar grab was collected at all four sites for determination of sediment TOC, BiS, and Chl. Monthly samples were also collected at H-31 in 1999 and at M-45 in 1999–2002. The top 0–1 cm of sediment was scraped from the surface of grab samples, freeze-dried, and analyzed as given above. Based on dated sediment cores collected in 2001, sediment accumulation rates at H-22 are about 1 cm·year\(^{-1}\) (J. Robbins, Great Lakes Environmental Research Laboratory, 2205 Commonwealth Boulevard, Ann Arbor, MI 48105, USA, unpublished data); thus, the 0–1 cm layer provided a good characterization of material deposited on an annual basis. Rates were likely less at the other 45 m sites, and this layer would therefore represent at least several years of accumulation. Grain size of sediment samples collected in 1998 was measured with a laser particle counter. Differences between years for individual constituents were tested with a one-way ANOVA, with sampling dates as within-year replicates.

Material collected in sediment traps consisted of material resuspended from the bottom by storm events and also of autochthonous material settled from the water column. To better define the latter source, a correction was made to calculated flux rates. Concentrations of TOC, BiS, and Chl measured for local surface sediment was subtracted from the concentration in the trapped material. This value was then multiplied by mass flux to produce an estimate of TOC, BiS, and Chl delivered to the site from sources other than local resuspension. Since not all sediment constituents were measured in 1997, corrections in that year were made based on 1998 values.

**Laboratory experiments**

Several laboratory experiments were conducted to provide insights into potential causes for the population decline. All experiments were conducted in a dark environmental chamber set at 4 °C. Purposes of the first experiment were to determine if sediments from a site where the population had recently disappeared were acutely toxic to *Diporeia* and to determine if these sediments had any nutritional value. Sediments were collected with a Ponar grab at two of the 45 m sites (H-31 and M-45) on 10 May 2000. At the time, mean densities of *Diporeia* were 0·m\(^{-2}\) and 6500·m\(^{-2}\) at the two
sites, respectively. The top 1 cm of sediment from each site was scraped from grab samples, placed into prerinsed glass jars (500 mL), and kept cool. Experimental animals at M-45 were collected by placing entire grab samples into plastic bags and kept at 4 °C until the experiments were initiated.

Within 24 h of collection, sediments from each site were washed through a 0.5 mm screen to remove macroinvertebrates, allowed to settle, and then placed into glass scintillation vials (20 mL). Enough sediment was placed in the vials to achieve a depth of 2 cm, which is similar to Diporeia’s normal burrowing depth. Vials were filled with filtered lake water (0.45 µm Millipore filter) that had been collected from near bottom at M-45. There were four treatments: filtered lake water only, medium sand, H-31 sediment, and M-45 sediment. The sand was prerinsed and ashed at 550 °C for 1 h. All vials were placed into an aquarium filled with filtered, aerated lake water and allowed to stabilize for 24 h. After the stabilization period, one animal (>5 mm) was placed into each vial, and the vial was then covered with nitex screen (mesh opening 0.5 mm) to prevent animals from escaping and yet allowing water exchange to take place. As animals were placed into the treatment vials, 28 animals were randomly selected and frozen for later analysis of lipid content. On 21 May (10 days), 30 May (19 days), 21 June (41 days), and 16 July (66 days), at least 10 vials from each of the four treatments were removed and the animal’s condition (live or dead) recorded. Lipid content of 5–10 living animals was measured as given above. Based on the volume of sediment in the vials (11.45 cm²) and typical ingestion rates (Dermott and Corning 1988), experimental animals would have ingested only a small fraction (<1%) of the provided sediment during the 66-day experiment. The results were analyzed using a two-way ANOVA (treatment × day) after arcsine transformation. In the analysis, initial lipid content (day 0) for each treatment was derived by randomly assigning lipid content of the 28 pre-experimental animals to the treatments (n = 7 per treatment).

The second experiment consisted of preference–avoidance trials with sediments from H-31 and M-45. The purpose of this experiment was to determine if Diporeia actively avoided sediments from H-31, a site where populations had recently disappeared. On 14 July 2000, sediments (0–1 cm) from both sites were collected with a Ponar grab, placed into plastic bags, and kept cool. Within 24 h of collection, sediments were screened and placed into labeled Petri dishes (47 mm diameter × 1.5 cm depth), with six dishes per site. Three dishes from each site along with three dishes with ashed sand (control) were randomly placed into each compartment of a two-compartment aquarium containing filtered lake water. Thus, there were duplicate trials, with each trial having three replicates per treatment. After a 24 h stabilization period, 100 Diporeia (collected at M-45) were placed into each compartment. Dishes were carefully removed after 120 h, sediments washed through a 500 µm mesh screen, and the number of animals burrowed into each dish recorded. Differences among the three treatments were determined using a one-way ANOVA followed by Tukey’s HSD. There were no significant differences between the two trials for each treatment (t test, df = 5, P > 0.05), so trial replicates were not distinguished in the ANOVA (n = 6 for each treatment).

Results

Density trends of major taxa groups in the southern basin, 1992–2002

Declines in Diporeia populations in the southern basin, which were initially documented in 1992–1993 (Nalepa et al. 1998), continued through 2002 (Table 1). Over the 1992–2002 period, significant differences in Diporeia densities occurred for years (F[3,1751] = 96.84, P = 0.0001), intervals (F[18,1751] = 249.50, P = 0.0001), and year × interval interaction (F[18,1751] = 11.95, P = 0.0001). Annual densities in 1998–2002 were not significantly different from each other but were significantly lower than densities found in 1992 and 1993 (P < 0.05, Tukey’s HSD). Mean densities at the <30, 31–50, and 51–90 m intervals decreased by 89.4%, 90.5%, and 44.6%, respectively, between 1992 and 2002. Declines were more pronounced on the east side of the basin than on the west side as lower densities, first observed in the southeastern portion of the basin in 1992, extended farther north and offshore over time (Fig. 2). By 2002, Diporeia were rare or completely gone to depths of at least 50 m in an area from near Chicago to Grand Haven. Of 23 sites sampled in 2002 that were in less than 50 m water depth, Diporeia were present only at Stations H-8, B-7, and EG-12, all on the west side of the basin (densities 3155·m–2, 4091·m–2, and 3150·m–2, respectively). Although still present, densities at these three sites in 2002 were lower than densities found in 1993 (declines of 46.2%, 46.2%, and 68.4%, respectively).

Whereas Diporeia continued to decline between 1992 and 2002, the dreissenid population became more widespread and abundant (Table 1). Differences in densities of Dreissena were significant for years (F[3,1751] = 13.43, P = 0.0001), intervals (F[3,1751] = 218.70, P = 0.0001), and year × interval interaction (F[18,1751] = 6.08, P = 0.0001). Over the 10-year period, dreissenids were mostly confined to depths <50 m, and greatest increases occurred at the 31–50 m interval. At this interval, mean densities of D. polymorpha increased from 7·m–2 in 1992 to 1112·m–2 in 2002. The other dreissenid species, D. bugensis, was first collected in the southern basin in 2001. By 2002, mean density at the 31–50 m interval had increased to 752·m–2 (Table 1). Mean density of the dreissenid population at the three west-side sites where Diporeia were still present in 2002 (H-8, B-7, and EG-12; total of nine replicates) were not significantly different from densities at the other 20 sites (total of 60 replicates) of similar depth (<50 m), where Diporeia had disappeared (t test, df = 67, P = 0.98, ln + 1 transformed).

Abundances of oligochaetes and sphaerids in the southern basin were documented only in 1992–1993 and 1998–1999 (Table 1). Differences in oligochaete densities were significant for years (F[3,1403] = 2.99, P = 0.03), intervals (F[3,1403] = 84.88, P = 0.0001), and year × interval interaction (F[9,1403] = 5.34, P = 0.0001). Densities in 1993 were significantly lower than the other 3 years (P = 0.03, Tukey’s HSD), but a consistent temporal trend over the entire 1992–1999 period was not apparent at any of the four intervals (Table 1). Sphaerid densities were also significantly different for years (F[3,1403] = 12.29, P = 0.0001), intervals (F[3,1403] = 156.25, P = 0.0001), and year × interval interaction (F[9,1403] = 9.48, P = 0.0001). The general trend was...
for a decline in densities at the two shallowest depth intervals over the period.

Comparisons of lakewide densities in 1994–1995 and 2000 indicated that declines of *Diporeia* occurred not only in the southern basin but also throughout the lake (Fig. 3). Mean lakewide density was 65% lower in 2000 compared with 1994–1995, and this difference was significant ($F_{[1,234]} = 53.38, P = 0.0001$). The decline occurred across all depth intervals, as the year × interval interaction was not significant ($F_{[3,234]} = 2.16, P = 0.09$). Densities at the <30, 31–50, 51–90, and >90 m intervals were 77.9%, 73.7%, 53.2%, and 51.6% lower, respectively (Table 2). Further, the extent of the decline was greatest in the northern region; the overall decline was 91.4% in the north compared with 65.0% and 42.4% in the south and central regions, respectively. While densities were lower in the north in each of the four depth intervals, a regional difference was only significant at the >90 m interval ($F_{[2,34]} = 8.58, P = 0.001$; Tukey’s HSD, $P < 0.003$). Lakewide densities of *Dreissena* were significantly higher in 2000 compared with 1994–1995 ($F_{[1,236]} = 38.04, P = 0.0001$). At sites <50 m, mean dreissenid densities were highest in the northern region in both sampling periods, which may explain greater declines of *Diporeia* in this portion of the lake.

### Annual density trends, 45 m sites

From the long-term monitoring program, densities of *Diporeia* were available for three of the 45 m sites (H-22, SAU-45, and H-31) in 1980–1981 and 1986–1987, which were the years just prior to the first report of *Dreissena* in Lake Michigan (first reported in 1989; Marsden et al. (1993)). Mean annual density of *Diporeia* by site and year ranged from 5347 to 14 044·m$^{-2}$ (Fig. 4). Beginning in 1992, the population declined systematically, first at the southern-most site (H-22) and later at the more northern sites. By fall 2002, *Diporeia* had disappeared from all four sites (Figs. 4, 5). Whereas *Diporeia* disappeared from each site within a 10-year period, rates and patterns of decline were site-specific. In 1992, densities at H-22 declined from 10 600·m$^{-2}$ in spring to 200·m$^{-2}$ in fall, a 98% decline in just 6 months. Declines to total loss were more gradual at the other 45 m sites, occurring between 1994 and 1999 at H-31 and between 1997 and 2002 at M-45. Unlike populations at the other 45 m sites, the population at M-45 recovered somewhat after initial declines were observed. Densities increased throughout 1999 and remained higher into spring 2000; however, densities decreased thereafter (Fig. 5). When considering all four 45 m sites, the period of time in which *Diporeia* declined from densities of 5300–14 000·m$^{-2}$ to <200·m$^{-2}$ varied from 0.5 to 5 years.

The relationship between annual densities of *Diporeia* and *Dreissena* was examined over the time period between just...
prior to initial declines and total disappearance. Densities of *Diporeia* and *Dreissena* were not well correlated at H-22; the population at this site collapsed in 1992 and totally disappeared by 1997, but *Dreissena* was not found at this site until 2000 (Table 3). At H-31 the relationship between the two taxa over the 1992–1999 period was not significant (linear regression; \( R^2 = 0.37, \ P = 0.11 \)), but the residuals indicated the presence of autocorrelation (Durbin-Watson D statistic = 0.966). Further analysis with a 1-year time lag (\( t - 1 \)) in *Dreissena* densities provided a significant relationship (\( R^2 = 0.70, \ P = 0.02, \) Durbin-Watson D statistic = 1.97). The relationship was improved when data from M-45 was included (Fig. 6).

**Recruitment and age classes, 45 m sites**

Because of limited availability of seasonal, size frequency data collected prior to declines at H-22 and SAU-45, meaningful analysis of density trends in the various age classes was only possible for populations at H-31 and M-45. As noted, declines in population density at H-31 were initially observed in 1994. Based on relative densities of YOY, juveniles, and adults, lower density in this year was a result of poor recruitment. Mean annual density of YOY in 1994 was only 215·m\(^{-2} \) (seasonal peak = 406·m\(^{-2} \)) compared with a range of 920–2438·m\(^{-2} \) (seasonal peak = 2411–4895·m\(^{-2} \)) in 1986–1993. In contrast, mean densities of juveniles and adults in 1994 were within the range found in 1986 to 1993 —
juvenile density was 3860 m⁻² in 1994 compared with 2004–4283 m⁻² in 1986–1993, and adult density was 3588 m⁻² in 1994 compared with 3462–7173 m⁻² in 1986–1993. Considering Diporeia have a 2-year life cycle at this depth in southeastern Lake Michigan (Winnell and White 1984), the lack of recruitment in 1994 likely accounted for lower juvenile densities observed in 1995 (Fig. 7). Recruitment in 1995–1997 was generally similar to recruitment in 1986–1993, as strong peaks in YOY occurred in 1995 (2438 m⁻²) and 1997 (2640 m⁻²), and although we only sampled on one date in 1996 (July), a relatively high density of YOY (2202 m⁻²) indicated recruitment also occurred in that year. Despite good recruitment, juvenile densities in these 3 years remained lower than found in 1986–1994, indicating poor YOY survival. Juvenile densities at H-31 subsequently collapsed in 1997, declining from 3300 m⁻² in early spring to 150 m⁻² in late fall. Adult densities remained stable in 1997 but declined in 1998, most likely a result of the lack of juveniles the previous year.

At M-45, annual recruitment occurred between 1997 and 2002, and peaks in YOY densities ranged from 1200 m⁻² to 4700 m⁻² (Fig. 8). Yet despite recruitment, juvenile densities generally declined each year, again indicating poor YOY survival. The exception to this pattern occurred in 1999. YOY survival was high in 1999 as evidenced by an increase in juvenile densities throughout the year, peaking at 3500 m⁻² in November; this accounted for the increase in population density in that year (Fig. 5). Juveniles continued to grow and survive through winter 2000 as evidenced by high adult density in spring 2000 (4000 m⁻²). Recruitment occurred in 2000, but as in 1997 and 1998, these recruits did not survive to become juveniles.

The number of eggs per gravid female was determined in spring 2001 at M-45 to determine if brood size had declined since the 1980s. In a 1981 study at a 42 m site in southeastern Lake Michigan, Winnell and White (1984) found that brood size ranged from 10 to 25 eggs per female and was directly related to female size. Brood size in 2001 varied from 21 to 32 eggs per gravid female (n = 7) and fit the same functional relationship to female size as in 1981.

**Lipid content and length–weight, 45 m sites**

When densities at the 45 m sites were declining, lipid content of juvenile and adult Diporeia tended to increase (Fig. 9). Detailed analysis of trends between density and lipid content were restricted to M-45, since densities at the other 45 m sites were already declining prior to 1997. Between 1997 and 2001, there was a significant difference.
between years \((F_{1,681} = 62.41, P = 0.0001)\), age classes \((F_{2,681} = 10.62, P = 0.0001)\), and year \times age class interaction \((F_{13,681} = 10.60, P = 0.0001)\). Yearly means in 1999–2001 were significantly higher than those in 1997–1998 \((P = 0.0001, \text{Tukey’s HSD})\), and lipid content in juveniles and adults were significantly higher than those in YOY \((P = 0.0001, \text{Tukey’s HSD})\). When just considering juveniles and adults, lipid levels increased from 21.6% ± 0.42% in 1997–1998 to 28.7% ± 0.56% in 1999–2001. Similarly, as densities declined at H-31 between 1997 and 1999, mean adult lipid content increased from 23.9% ± 0.6% in 1997 to 34.7% ± 2.1% in 1999. The relationship between lipid content and density can be put into a more long-term perspective by examining trends at H-31 beginning in the 1980s (Fig. 4). Seasonal trends in lipid content of adult Diporeia were measured at this site in 1984, 1986, 1988, and 1989 (Gardner et al. 1985b; Gauvin et al. 1989; Cavaletto et al. 1996). Mean annual lipid content in 1984–1989 varied from 26% to 32%. When density declines were first observed in 1994, mean lipid content was only 15%. As densities continued to decline after 1994, lipid content increased each successive year until by 1998–1999 lipid values were as high as found in the 1980s.

Lipid content in juveniles and adults generally peaked in spring or summer and then declined in fall (Fig. 9). Seasonal peaks in late spring – summer were consistent with the premise that intensive feeding during the spring diatom bloom results in the storage of energy as lipids (Gardner et al. 1985b, 1990). To determine if seasonal peaks in 1997–2001 were comparable with those found in 1984–1989 (adults only), the seasonal maximum was divided by the early spring minimum and the ratio was compared between the two periods. For the 1997–2001 period, only those sites and years in which adults were collected throughout the year were included. The mean ratio was 1.31 ± 0.07 (\(n = 8\)) in 1997–2001 and 1.58 ± 0.28 (\(n = 4\)) in 1984–1989. Although lower in the 1997–2001 period, the difference was not significant (t test; \(P > 0.05\)).

In deepwater amphipods, weight per unit length generally declines when animals are food-limited (Hill et al. 1992; Lehtonen 1996). The relationship between lipid-free dry weight \((\text{LFDW in mg})\) and length \((L\ \text{in mm})\) was defined by \(\text{LFDW} = aL^b\) and was determined annually for each 45 m site over the 1994–2001 period (Table 4). All regressions were significant (range of \(R^2\): 0.56–0.96). When LFDW for a standard 5 mm animal was calculated, yearly trends were not apparent (Table 4).

### Sedimentation rates and sediment variables

Sediment traps, deployed at the 45 m sites in 1997–1999, documented amounts of organic material settling to the bottom that potentially served as a food source for Diporeia. In general, there was a consistent primary peak of TOC, BiS, and Chl in spring and a secondary peak in fall at each of the sites (Fig. 10). Most relevant to Diporeia populations were flux rates associated with the spring peaks; these peaks are enriched in organic materials (diatoms) compared with peaks in the fall (Scavia and Fahnkenstiel 1987; Gardner et al. 1990).

### Table 2. Mean (± standard error) densities (no.·m⁻²) of Diporeia and Dreissena at four depth intervals in Lake Michigan in three different regions in 1994–1995 and 2000.

**Note:** See Nalepa et al. (2000) for delineation of regions. Values in parenthesis are numbers of sites sampled in 1994–1995 and 2000, respectively, within each depth interval and lake region. In 1994–1995, all Dreissena were *D. polymorpha*; in 2000, 98.3% were *D. polymorpha* and 1.7% were *D. bugensis*.© 2006 NRC Canada
Fig. 4. Density (no.·m\(^{-2}\)) of Diporeia spp. at three 45 m sites in southeastern Lake Michigan, 1980–2002: (a) H-31, (b) SAU-45, (c) H-22. The broken lines at H-31 give the lipid content (percent dry weight) of Diporeia spp. at this site.

1989). Over the 1997–1999 period, the magnitude of spring peaks at H-31 and M-45 decreased for all constituents (Fig. 10). In spring 1997, the spring average (March–May) flux rates of TOC at these two sites were 434 and 461 mg·m\(^{-2}\)·day\(^{-1}\), respectively, and flux rates of BiS were 1176 and 1199 mg·m\(^{-2}\)·day\(^{-1}\), respectively. In contrast, spring 1999 flux rates of TOC were only 88 and 57 mg·m\(^{-2}\)·day\(^{-1}\), and flux rates of BiS were 181 and 45 mg·m\(^{-2}\)·day\(^{-1}\), respectively, for sites H-31 and M-45. Low flux rates in 1999 were mostly related to quantitative changes in inputs, as nutrient content of collected material was generally higher in 1999 than in previous years (Table 5). Further, mean annual C/N ratio (weight) did not show a consistent trend at these two sites over the same period; the ratio tended to increase at M-45 but not at H-31. In 1998 when flux rates were measured at all four 45 m sites, spring average flux rates of all constituents increased on a spatial gradient from south to north, being lowest at H-22 and highest at M-45 (Fig. 10), while the mean C/N ratio decreased along the same gradient (Table 5).

Sediment composition varied widely at the 45 m sites, ranging from predominately silt at the southern-most site (H-22) to sand at the northern-most site (M-45). The percent

Note: Standard errors depict variability between sampling dates.

Fig. 5. Mean density (no.·m\(^{-2}\)) of Diporeia spp. on each sampling date at three 45 m sites in 1997–2002. Although not shown, no Diporeia were collected at the other 45 m site (H-22) during the sampling period. Error bars denote standard error. △, SAU-45; ○, H-31; ●, M-45.

Fig. 6. Relationship between mean annual density (no.·m\(^{-2}\)) of Diporeia spp. and Dreissena at H-31 (●) and M-45 (○). Dreissena densities are given as a 1-year time lag (t – 1). Sampling periods were 1992–1999 for H-31 and 1997–2002 for M-45 (linear regression $R^2 = 0.59$, $P = 0.003$, $n = 12$).
clay, silt, and sand was, respectively, 2.3%, 85.7%, and 12.0% at H-22; 1.9%, 53.2%, and 44.9% at SAU-45; 1.7%, 31.3%, and 67.0% at H-31; and 0.7%, 15.2%, and 84.1% at M-45. Nutrient content of the upper 0–1 cm decreased from south to north as grain size increased. In 1998 mean sediment concentrations of TOC, BiS, and Chl were 4-, 6-, and 3.5-times greater, respectively, at H-22 than at M-45 (Table 5). Continued sampling at H-31 to 2000 and at M-45 to 2002 indicated nutrient content increased over levels found in 1998. At H-31 there was a significant difference between years (1998–2000) for BiS ($F_{[2,11]} = 4.406, P = 0.039$), and at M-45 there was a significant difference between years (1998–2002) for TOC ($F_{[4,29]} = 12.43, P = 0.0001$), BiS ($F_{[4,29]} = 18.77, P = 0.0001$), and CHl ($F_{[4,29]} = 11.122, P = 0.0001$). The increase at M-45 was such that in 2002, concentrations of BiS and Chl were not significantly different from values found at H-22 in 1998 ($t$ test, $df = 15, P = 0.239$ for BiS; $P = 0.79$ for Chl). As nutrient content increased, there was no apparent trend in the C/N ratio (Table 5).

**Laboratory experiments**

Mortality in the 66-day starvation experiments was low in all four treatments. Of the 191 animals retrieved from filtered lake water, ashed sand, H-31 sediments, and M-45 sediments, only five were found dead during the entire experimental period. Lipid content declined in all four treatments during the experimental period (Table 6). Mean initial lipid content was 31.8% on day 0, and final lipid content ranged from 21.3% (H-31 sediment) to 25.2% (sand) on day
There was a significant difference between dates ($F_{[4,109]} = 6.46, P = 0.0001$), but date × treatment interaction was not significant ($F_{[12,109]} = 0.95, P = 0.50$), indicating no difference in treatment effects. On the date experiments ended (16 July), mean lipid content of freshly collected adults at M-45 was 27.4%. The greater lipid value of in situ animals suggested access to nutritional material not available to laboratory animals.

In the preference–avoidance experiments, 95 of 100 and 92 of 100 animals were recovered in the two trials, respectively. Mortality was minimal (only 6 of 187), and all living animals were found burrowed in the substrate rather than swimming in the overlying waters. Mean (± standard error, SE) numbers of animals burrowed in sand, H-31 sediment, and M-45 sediment were 0 ± 0, 14.5 ± 2.5, and 15.7 ± 3.5, respectively. Numbers found in the two sediment treatments were not significantly different, and numbers in both sediment treatments were significantly higher than numbers found in the sand treatment ($F_{[2,15]} = 12.268, P = 0.001$, Tukey’s HSD). When sediments for these experiments were collected (July 2000), the Diporeia population had already disappeared from H-31, but was still present at M-45. Given these laboratory results, the disappearance from H-31 was not likely due to animals actively avoiding the sediments per se.

### Discussion

On a broad scale, the decline of Diporeia in Lake Michigan in the 1990s was closely related to the expansion of dreissenid populations within the lake. In the southern basin, greatest declines occurred in the 30–50 m depth interval where dreissenid densities increased to the greatest extent. Also, declines lakewide were most extensive in the northern portion of the lake where dreissenid densities were higher than in more southern portions. Yet on a local scale, inconsistencies were apparent. Whereas Diporeia and dreissenids were negatively correlated at several sites, Diporeia remained abundant at some sites despite the long-term presence of dreissenids, but yet declined rapidly at a site with no dreissenids. Our field observations and laboratory experiments failed to establish a clear, direct relationship between the loss of Diporeia and indicators of food availability. From our results, several questions pertinent to the food-limitation hypothesis remain enigmatic.

(i) Why did the Diporeia population collapse so completely in an area where there were no mussels and where at least some pelagic food material was still likely settling to the benthic region? (ii) Why did lipid content, which is an indicator of energy reserves and directly related to food availability, remain at high levels as the population disappeared? In areas where dreissenids were not present or found in low numbers, such as at H-22, sediment traps should accurately reflect pelagic inputs to the upper sediments. That is, mussels at the sediment surface would not be intercepting settling organic material prior to becoming available to Diporeia feeding in the upper sediments. Diporeia at H-22 completely disappeared by 1997, yet based on trap flux rates of TOC, BiS, and Chl in 1998, at least some organic material was still settling to the bottom. Others have also documented a collapse of Diporeia populations in areas far removed from Dreissena colonies and where potential food was still found in the water column (Dermott 2001; Nalepa et al. 2003). Dermott (2001) theorized that the remote loss of Diporeia might be a function of their spatial distributions relative to dreissenid beds and dominant current patterns. Particulate organic material in water flowing over dreissenid beds would be removed by mussel filtration and unavailable to Diporeia located in areas downcurrent. In the Hudson River, Strayer and Smith (2001) suggested that the upstream removal of organic material by dense dreissenid colonies led to the severe decline of microzooplankton in areas downstream with few mussels. This, in turn, led to the extirpation of downstream Chaoborus populations, which relied on microzooplankton as a food source. Even so, it is difficult to reconcile how the remote removal of potential food by
vier years prior to ingestion rates, assimilation rates, and lipid levels were closely linked to water column productivity at 45 m in the immediate overlying waters. This seems unlikely, since on inputs from the nearshore than pelagic inputs from the deepest regions of the Great Lakes where benthic food historically been the dominant benthic macroinvertebrate in

**Note:** The relationship is defined by \( \ln \text{LFDW} = a + b \ln \text{L} \), where LFDW is lipid-free dry weight (mg), and L is body length (mm). Standard error is given in parentheses. n is the total number of animals analyzed. The lipid-free dry weight of a standard 5 mm animal is given.

Our laboratory experiments indicated that sediments from H-31 and M-45 did not have an adverse impact on Diporeia per se. Mortality was not observed after a 66-day exposure, and the sediments were not actively avoided. Interestingly,

The disappearance of Diporeia at H-31 and M-45 was more gradual (5 years) than at H-22 and well correlated to an increase in the Dreissena population. Given this close temporal association, food limitation may indeed have played a major role in the loss of Diporeia at these sites. Yet flux rates of constituents indicative of food inputs during the period of initial declines were similar to rates reported prior to Dreissena. For instance, the population at H-31 began to decline in 1994 and collapsed in 1997 and 1998, while the population at M-45 began to decline in 1997. In 1997 and 1998, average spring flux rates of TOC at these two sites varied from 273 to 461 mg·m⁻²·day⁻¹, which were comparable with rates of 288 and 430 mg·m⁻²·day⁻¹ found at H-31 in 1986 and 1990, respectively (B.J. Eadie, unpublished data). Uncorrected mean spring flux rates of BiS in 1997–1998 were 433–1500 mg·m⁻²·day⁻¹. These rates were generally similar to or greater than an uncorrected mean spring flux rate of 475 mg·m⁻²·day⁻¹ found at H-31 in 1986 (Gardner et al. 1989). Populations were already declining in 1999 when far lower flux rates of all constituents were observed. Low flux rates in 1999 were likely a result of an uncommon occurrence rather than the beginning of a trend. In most years, water column Chl peaks in spring, but in 1999, the peak occurred in early winter (B.J. Eadie, unpublished data). Thus, we likely missed the spring diatom peak with our deployment in 1999. As noted, sediment traps do not reflect pelagic inputs to the upper sediments in areas where Dreissena densities are high. Dreissena densities were >500·m⁻² in 1997 at H-31 when the Diporeia population collapsed, but <50·m⁻² in 1994 when initial declines were observed. Thus, despite high pelagic inputs that were still likely present in 1994, even low densities of Dreissena had a negative impact on Diporeia.

The relationship between lipid-free dry weight and length for Diporeia at each of the 45 m sampling sites in each year lipid content was measured.
whereas there was no mortality during the laboratory experiments, the population of Diporeia at M-45 declined by 66% over the same 66-day period (May to July). Thus, conditions that led to the decline at M-45 were not duplicated in the laboratory using sediments from the same site and animals from the same population. This may imply that the population was reacting negatively en masse to the physical deposition of organic material in the spring. As noted, the rapid decline at H-22 was similarly observed after the spring period. Sediments from H-31 and M-45 were not acutely toxic to Diporeia, the same result found for sediments from H-22 (Landrum et al. 2000).

If food limitation was the primary cause for the loss of Diporeia, then the animals should show some physiological signs of starvation before or during the period of population loss. In deepwater amphipods, lipid levels are a good indicator of food availability; levels increase just after the spring diatom bloom when food is readily available and decline during periods of low benthic food inputs in late summer and winter (Gardner et al. 1985b; Hill et al. 1992; Lehtonen 1996). When the population began to decline at H-31 in 1994, mean annual lipid content was only 15%, and the spring lipid peak was only 17%. These values indicate severe starvation — similar levels were found in laboratory animals starved for 120 days (Gauvin et al. 1989). Recruitment was poor in 1994, which is consistent with the suggestion that lipid values below 20% lead to reproductive failure (Hill et al. 1992). As densities continued to decline after 1994, lipid content unexpectedly increased and annual recruitment occurred. Possibly, lipid content increased because declining densities led to more food for remaining organisms. Yet if this were so, then poor YOY survival should not have occurred, and the population should have stabilized at some reduced level consistent with a diminished food supply. Further, the increase in dreissenids over this period would have further reduced available food and resulted in lower rather than higher lipid values. As Diporeia densities approached zero in 1999, lipid levels were over 30% and comparable with levels found at this site in the 1980s just after the spring diatom bloom (Gardner et al. 1985b; Cavaletto et al. 1996).

While the long-term decrease and then increase in lipid content found at H-31 has not been previously documented in field populations, such a pattern was found in animals
starved in the laboratory (Gauvin et al. 1989). In these experiments, lipid content declined from 30% to 12% after 120 days and then increased to 18% after 191 days. The increase was attributed to the selective catabolism of non-lipid material (tissue components) after storage lipids were utilized. Weight-specific lipid content may thus increase even though absolute lipid content and total weight may decrease. This possibility seems to be refuted by the consistency in non-lipid weight (relative to length) at the 45 m sites over the time period when lipids increased. Further, absolute lipid content remained stable or actually increased during this period (Fig. 11). Under some circumstances, an increase in lipid content may reflect an interference with lipid degradation or lipid transport processes (Giesy et al. 1988). Accumulated lipids would thus remain unutilized as an energy source during periods of low food availability. The decline in lipid content and lack of mortality during the 66-day food-deprivation experiments indicated, however, that the animals were still able to utilize lipid material as an energy source. The increase and relatively high lipid content at the 45 m sites as populations disappeared suggests that biochemical–physiological changes were occurring in the animals, but the cause and meaning of such changes remain unresolved.

When *Diporeia* were declining, adult fecundity (eggs per brood) was similar to that found in the 1980s when abundances were high. Except in 1994, these young developed and were recruited into the population. Population declines after 1994 occurred because the YOY were not surviving to become juveniles; that is, annual peaks in YOY were generally not followed by increased numbers of juveniles. Eventually, declines in adults resulted from reduced numbers of juveniles rather than adult-specific mortality. Because of higher metabolic and growth rates, YOY are more sensitive

---

Fig. 11. Mean (± standard error) lipid content (mg) of juvenile (○ - ○) and adult (● — ●) Diporeia spp. at (a) M-45 and (b) H-31 over the period of declining densities at both sites.

The decline of Diporeia in Lake Michigan, first observed in 1992, continued through 2002. This decline represents a major loss of energy to upper trophic levels. For example, most fish in Lake Michigan are found at depths <90 m.

Erie after dreissenid colonization was attributed to the accumulation of mussel biodeposits (Howell et al. 1996).

If food limitation was the cause of declines in Diporeia, then dreissenid biodeposits must not be available as a nutrient source. Either biodeposits are too refractive to sustain Diporeia, or biodeposits are somehow having a negative impact. In laboratory microcosms, Diporeia survival was reduced by 25% when exposed to mussel pseudofeces for 90 days (Dermott et al. 2005), so perhaps there is a direct negative response. In contrast, oligochaete densities remained stable between 1993 and 1999, which may reflect an ability to utilize this material as a food source. Whether oligochaetes will persist at these densities remains unclear. In Lake Ontario, where the dreissenid expansion occurred earlier than in Lake Michigan, oligochaete densities have recently declined (Lozano et al. 2001).

Although the loss of Diporeia in the Great Lakes has been extensive since Dreissena became established, these two taxa do seem to coexist in some areas. In the Finger Lakes, New York, Diporeia abundances have not decreased despite an increase in dreissenids over the same time period (Dermott et al. 2005). In Lake Michigan, Diporeia continue to be present (although in reduced numbers) at a site <30 m on the western side of the southern basin despite the presence of dreissenids. Upwellings are more frequent on the west side (Plattner et al. 2006), which create conditions of lower temperature and higher productivity that are favorable to Diporeia. Lower temperatures associated with upwelling cannot entirely explain the continued presence of Diporeia at this shallow, west-side site — populations on the east side disappeared at depths below the thermocline (>30 m) where temperatures were as consistently cold as shallow areas on the west side subject to upwellings. The persistence of Diporeia at this site may be temporary, but it does further illustrate the inconsistency associated with temporal and spatial patterns of decline.

Similar to declines of Diporeia in the Great Lakes, the related deepwater amphipod Monoporeia is also declining in the Baltic Sea (Perus and Bonsdorff 2004). Interestingly, circumstances associated with Monoporeia’s decline, as well as uncertainties of potential causes, closely parallel those for Diporeia. The decline of Monoporeia in most areas was temporally coincident with the invasion of the Baltic by the polychaete Marenzelleria viridis (Perus and Bonsdorff 2004). This polychaete is a detritivore and believed to be competing directly with Monoporeia for available food resources. Yet the decline in Monoporeia was greater in offshore areas (>30 m) than in nearshore areas, even though densities of Marenzelleria were greater in the latter (Cederwall et al. 1999). Low oxygen levels have been suggested as the reason for the decline in offshore waters, but others suggest it is food limitation (Cederwall et al. 1999; Kotta and Olafsson 2003). Also, in some parts of the Baltic, the collapse of Monoporeia occurred prior to the establishment of Marenzelleria (B. Sundelin, Department of Applied Environmental Science, Stockholm University, SE-106 91 Stockholm, Sweden, personal communication).

Nutrient content of the sediments (TOC, BiS, Chl) increased during the study period. Most likely, these increases were a result of dreissenid filtering activities rather than a result of reduced utilization by declining Diporeia populations. BiS associated with diatom frustules remains unchanged when consumed by pelagic or benthic grazers, and thus any sediment increase must reflect increased accumulation from the water column. Dreissenids effectively filter fine particulate material from the water column that otherwise would not easily settle; unassimilated material is then deposited in the form of mussel feces and pseudofeces. A 4- to 8-fold increase in sediment concentration of TOC in nearshore Lake Erie after dreissenid colonization was attributed to the accumulation of mussel biodeposits (Howell et al. 1996).

to declines in food levels than adults. In laboratory experiments assessing food competition between YOY and adults, YOY mortality was high at low to medium food regimes, whereas adults were not affected (Hill 1992; Wenngren and Olafsson 2002). Annual fluctuations in Monoporeia densities have been attributed to high mortality of YOY because of intraspecific competition for food with adults (Johnson and Wiederholm 1989; Sarvala 1986). Initial declines of juveniles relative to adults at the 45 m sites suggest that food limitation may indeed be a cause of the population decline, at least at these sites. Inconsistent with this premise is that lipid content of juveniles remained high and displayed spring peaks even as numbers decreased.

Nutrient content of the sediments (TOC, BiS, Chl) increased during the study period. Most likely, these increases were a result of dreissenid filtering activities rather than a result of reduced utilization by declining Diporeia populations. BiS associated with diatom frustules remains unchanged when consumed by pelagic or benthic grazers, and thus any sediment increase must reflect increased accumulation from the water column. Dreissenids effectively filter fine particulate material from the water column that otherwise would not easily settle; unassimilated material is then deposited in the form of mussel feces and pseudofeces. A 4- to 8-fold increase in sediment concentration of TOC in nearshore Lake
(Wells 1968). In 1994–1995, mean dry weight biomass \( B \) of Diporeia at depths <90 m was 4.8 g·m\(^{-2}\) (Nalepa et al. 2000). Lakewide production \( P \) at <90 m was thus calculated as 7.7 g·m\(^{-2}\) (assuming \( P = B \times T^2/10 \) (Johnson and Brinkhurst 1971) and a mean temperature \( T \) of 4 °C). Further assuming that differences in size frequencies and lengths–weights of the Diporeia population were minimal between 1994–1995 and 2000, the amount of secondary production lost to fish over this period was 5.1 g·m\(^{-2}\). While this represents a substantial loss, the decline of Diporeia has other implications to the fish community besides the loss of a major producer of secondary biomass. Diporeia have a higher lipid content and therefore more calories than most other invertebrate prey items. So even if fish switch to other prey, fish bioenergetics will still likely be affected. As evidence, condition and growth of lake whitefish have declined since the loss of Diporeia even though alternate prey have been found in their stomachs (Pothoven et al. 2001; Hoyle et al. 2003). A decrease in energy density and (or) lipid content of fish species that serve as prey for the larger piscivores, such as alewife and sculpin, have been attributed to the decline of Diporeia (Madenjian et al. 2003; Hondorp et al. 2005). The recent introduction and expansion of quagga mussels into deeper regions of Lake Michigan will likely lead to further declines in Diporeia and, hence, further impacts on fish populations.

In summary, features of declining Diporeia populations in Lake Michigan were highly variable. Depending on the site, declines in abundances were rapid and apparent in all age classes, or declines were more extended and mostly a result of poor juvenile survival. The former suggests mass mortality in response to perhaps a dreissenid toxic agent, whereas the latter suggests possible food limitation from dreissenid filtering activities. Our quantitative and limited qualitative measures of benthic food inputs, along with observed changes in physiological well-being and laboratory mortality–avoidance experiments, failed to provide conclusive evidence of a cause. Inconsistencies apparent in our results may imply a multitude of causative factors whose relative importance may vary depending on specific environmental conditions. If food limitation is the sole cause, then a nutritional problem, not evident from our measures of gross food inputs or physiological well-being, is a possibility. Given this, detailed studies of cellular or biochemical indicators may prove worthwhile. For instance, profiles of essential fatty acids (Brett and Mulder-Navaara 1997) or functional protein groups (Lopez et al. 2001) in areas with declining and stable populations may show differences specific to nutritional deficiencies or to disease–defense mechanisms. Populations from areas subject to upwelling–downwelling and high–low sedimentation would be of particular interest. By better understanding reasons for Diporeia’s decline relative to increased numbers of dreissenids, we may better predict the eventual extent and ultimate consequences of the population loss.
